**Total Budget for FY2006-FY2010**  180,201,000Yen
(FY2010; 36,503,000Yen)

**Key Words**  Greenhouse Gases, Commercial Airliner, Asian-Pacific Region, Vertical Profile, Frequent Observation

1. Introduction

The inverse approach by atmospheric transport model is one of the most reliable way to estimate the temporal and spatial variations of CO₂ fluxes. Major limitation of the inverse approach is the low density of atmospheric CO₂ concentration measurement. Substantial efforts are made to measure atmospheric CO₂ in the world. In comparison with the surface air observations, CO₂ measurements above the planetary boundary layer (PBL) are sparse due to the limited number of aircraft observations. Research aircraft campaigns using on-board measuring systems provided a detailed CO₂ distribution in the free troposphere. But expense and the snap-shot nature of research aircraft campaigns mean that the climatology in spatial and temporal CO₂ variabilities above the PBL have not been well defined in comparison with surface air measurements. Commercial airliner is one of the ideal platform to measure atmospheric CO₂ and other trace gases in the upper air in high frequency and wide area-coverage.

2. Research Objective

Regular air sampling using Boeing 747 commercial airliner has been carried out since 1993 to observe CO₂, CH₄ and CO mixing ratios between Japan and Australia. We extend the observation to conduct the in-situ CO₂ measurement onboard the aircraft operated by Japan Airlines (JAL) and reveal the spatial and temporal variation of CO₂ over South East Asia and East Asia as well as Europe, North America, Pacific and Australia. Obtained data are useful not only for solving global carbon cycles but also for understanding atmospheric air transport and for validating satellite CO₂ measurements such as GOSAT.

3. Research Method
We use Continuous CO₂ Measurement Equipment (CME) and improved Automatic Air Sampling Equipment (ASE). CME can be installed on two 747-400 aircraft and three 777-200 aircraft. CME continuously measure CO₂ during 1-1.5 months onboard and obtain vertical profiles during ascending and descending, and horizontal distributions in upper air during the cruise. ASE can be installed on two 747-400. ASE get air samples over the pacific during the flight from Sydney to Narita twice a month. Air sample is analyzed for concentrations of CO₂, CH₄, CO, N₂O, SF₆ and H₂ and stable isotope ratio of CO₂ and CH₄.

4. Results and Discussion

During the period from November 2005 to March 2011, more than 10000 vertical profiles have been obtained. Figure 1 shows the flight routes, airport code for flight destination and the number of vertical profiles obtained.

Since April 2009, a manual sampling equipment (MSE) was used to continue flask sampling observations for measuring CO₂, CH₄, CO, N₂O, SF₆ and H₂ at about 10 km altitude between Australia and Japan.

A new ASE and MSE were used to conduct atmospheric measurements of CO₂, CH₄, CO, N₂O, SF₆ and H₂ at about 10km altitude by using JAL airliner between Australia and Japan during December 2005 – December 2010. On the basis of these measurements, the time-series data analyses for 12 latitudinal bands between 30N and 30S were made. The recent long-term trends during the past 5 years were well captured in the both hemispheres over the western Pacific. In addition, seasonal cycles and their latitudinal changes of CO₂, CH₄ and CO were clearly observed, although very small amplitudes of the seasonal cycles were found in N₂O and SF₆. The long-term trends and seasonal cycles of CO₂, CH₄ and CO from the new ASE were consistent with those from the climatology of previous observations since 1993 (Figure 2). These results demonstrate the consistency in the continuity of the CO₂, CH₄ and CO records extended by the present study. All of
the present and past measurements were re-calculated based on the same standard scales, and then combined to make high-quality integrated databases for the past 18 years from 1993 to 2010. The CO₂ dataset was posted on the world data centers operated by the WMO/JMA and NOAA/ESRL. The data were used for validating model transports and satellite observations, and their results were published by collaborative studies.

Figure 2. Time variations of CO₂ divided into 12 latitudinal bands at 10 km over the western Pacific from April 1993 to December 2010 based on the high-quality database integrated by the present and past JAL airliner observations.

Figure 3 shows the seasonal variations of CO₂ over North Europe, Moscow, Vancouver, Delhi, Narita, Honolulu, Bangkok, Singapore and Sydney. Large seasonal amplitudes were observed over Moscow, due to direct influence of biospheric activities around there. Seasonal variations in free troposphere are almost constant along the altitude over Honolulu, which located on small island in the Pacific ocean. Higher CO₂ were found at lower altitude over Bangkok from January to March. Biomass burnings around Bangkok might enhance CO₂ mixing ratios in that season. Small but clear seasonal variations with the phase in Northern Hemisphere were found over Singapore even though it is located near Equator. The seasonal variations over Sydney were opposite in phase with those in Northern Hemisphere.
Variations of CO₂ in the tropopause region were analyzed. The data were obtained from flights between Japan and Europe during the period November 2005 to December 2010. The local phase and amplitude of the CO₂ seasonal cycle varied with distance from the tropopause. In the upper troposphere and in the region just above the tropopause, a strong seasonal cycle with a springtime maximum and a relatively sharp minimum in July was observed. In the region greater than 30K in potential temperature from the tropopause, sharp CO₂ increases in summer followed by gradual
decreases were found, resulting in a slightly increasing seasonal cycle amplitude with distance from the tropopause. The observed CO₂ distributions also showed that CO₂ isopleths followed the tropopause during the winter and spring, whereas in the summer they tracked potential temperature surfaces crossing the tropopause. The observed seasonal variation in CO₂ suggests that the lowermost stratospheric region is influenced by a combination of (1) fast meridional transport of high CO₂ from the tropical troposphere in the summer, (2) relatively weak vertical mixing in the winter and fall, and (3) active subsidence of low CO₂ from higher altitudes in the spring.

Observed mixing ratios were integrated for a reference year of 2008 to plot climatological distributions of CO₂ in the upper troposphere. Strong seasonal cycles with springtime maximums and relatively sharp minimums in July are found in the mid-, high latitudinal regions in the upper troposphere. Longitudinal differences of CO₂ mixing ratios in the mid-, high latitude were relatively small in winter season, but significant differences were found in summer. The mixing ratio begins to decrease slightly in May, reaching a minimum value in July over Eurasian continent. On the other hand, the mixing ratio over the North Pacific begins to decrease after one month delay, suggesting the transport of low CO₂ originated from terrestrial sinks to oceanic regions. CO₂ cross sections by using the flights between Japan and Australia or Southeast Asia show spread of high mixing ratios from the Northern Hemisphere to the Southern Hemisphere from April in the upper troposphere. This transport brings increase of CO₂ of about 0.7 PgC in 600-200hPa, Eq.-30S in the Southern Hemisphere.

Figure 5. CO₂ distributions in the upper troposphere between 8 km and tropopause. CO₂ mixing ratios are converted to the values for a reference year of 2008 assuming the trend.
